**Abstract** The hypoxia inducible factor 1 alpha (HIF1a) is a key regulator of tumour cell response to hypoxia, orchestrating mechanisms known to be involved in cancer aggressiveness and metastatic behaviour. In this study we sought to evaluate the association of a functional genetic polymorphism in **HIF1A** with overall and metastatic prostate cancer (PCa) risk and with response to androgen deprivation therapy (ADT).

The **HIF1A** \(+1772\) C>T \((\text{rs11549465})\) polymorphism was genotyped, using DNA isolated from peripheral blood, in 1490 male subjects (754 with prostate cancer and 736 cancer-free) through Real-Time PCR. A nested group of cancer patients who were eligible for androgen deprivation therapy was followed up. Univariate and multivariate models were used to analyse the response to hormonal treatment and the risk for developing distant metastasis. Age-adjusted odds ratios were calculated to evaluate prostate cancer risk.

Our results showed that patients under ADT carrying the **HIF1A** +1772 T-allele have increased risk for developing distant metastasis (OR, 2.0; 95%CI, 1.1–3.9) and an independent 6-fold increased risk for resistance to ADT after multivariate analysis (OR, 6.0; 95%CI, 2.2–16.8). This polymorphism was not associated with increased risk for being diagnosed with prostate cancer (OR, 0.9; 95%CI, 0.7–1.2).
1. Introduction

Prostate cancer (PCa) remains a major public health concern because it is the most common malignant neoplasm and the second leading cause of cancer death in men [1].

Clinically, it is a heterogeneous disease, with aggressiveness risk differing greatly among individuals despite similar clinical and pathological characteristics. Currently, only incipient but scarce markers help to predict whether PCa will be an aggressive, fast growing disease or an indolent slow growing type of cancer [2]. Therefore, new strategies to help clinicians distinguish between lethal and indolent prostate cancer are needed. Recent findings indicate that genetic variants may predispose to more aggressive prostate cancer [3–5], which is supported by epidemiological studies that propose genetic background influences cancer prognosis [6–8]. Recent genome-wide association studies (GWAS) revealed numerous genetic variants associated with prostate cancer risk, although only little discriminatory ability was shown for fatal forms of the disease [9].

Intratumoural hypoxia is a hallmark of solid neoplasias. It is well established that hypoxic tumour microenvironment initiates multiple cellular responses, ultimately resulting in cancer progression [10,11]. The hypoxia inducible factor 1 alpha (HIF1α) is a transcription factor coded by the HIF1A gene that regulates cellular response to hypoxia [12,13], inducing cancer progression through activation of many genes involved in regulatory cancer biology (angiogenesis, cell metabolism, cell survival, and epithelial-to-mesenchymal transition) [14]. The HIF1A gene harbours several SNPs, including a C-to-T substitution at locus +1772 that result in aminoacid modification (proline by serine). Previous in vitro studies showed higher transcriptional activity of the variant allele under both normoxic and hypoxic conditions [12,14], whereas additional research associated this SNP with increased tumour microvessel density [12,14,15].

Recent studies yielded conflicting results regarding the involvement of HIF1A +1772 C>T genetic polymorphism in cancer, albeit a significant positive association remained after meta-analysis in Caucasian women specific cancers [16,17]. In prostate cancer, the few studies were conducted in distinct ethnic populations and clinicopathological characteristics leading to conflicting results [16,18,19]. Furthermore, the association of HIF1A +1772 C>T SNP with prostate cancer progression, metastasis and refractoriness to androgen deprivation therapy (ADT) merits further evaluation in larger series of patients. In the present study we sought to analyse the association of the functional SNP +1772 C>T in HIF1A with PCa using prostatic biopsy-proven controls, and to predict the response to treatment in men receiving ADT.

2. Patients and methods

2.1. Patients

Subjects with histological confirmation, whether on biopsy or surgical specimen, of prostate cancer (n = 754) or absence of malignancy (n = 736) were included in a case-control study. Patients were recruited from five Hospitals in Portugal between 1990 and 2009: Portuguese Institute of Oncology – Porto Centre, S. João Hospital, Porto Military Hospital, Porto Hospital Centre, and Central Lisbon Hospital Centre. The study was approved by hospital’s research ethics committees and consent obtained from participants.

The non-PCa control group comprises men referred for prostate biopsy (8–13 cores) on the basis of abnormal digital rectal examination and/or single baseline PSA levels over 2.5 ng/ml, but with normal or benign prostatic histology. Subjects without malignancy at biopsy (BPH or chronic prostatitis) were considered controls since (1) diagnosis was contemporary, (2) were age matched with elderly cancer patients, (3) all were submitted to digital rectal examination, PSA estimate and prostatic biopsy, making remote the possibility of crossover, (4) most men have benign diseases of the prostate by the 7th–8th decades of life, making it normal in men of that age, (5) bias would be expectable if only men without prostatic disease were eligible, because of the much younger range of ages. Patients with high-grade prostatic intraepithelial neoplasia or a biopsy suspicious of cancer were excluded.

A nested sample of subjects from the group of PCa patients (those eligible for androgen deprivation therapy, ADT, (n = 429) was followed up for several years. These patients were submitted to orchiectomy or luteinising hormone releasing hormone agonist (LHRHa) (with or without anti-androgen) immediately after diagnosis or after relapsing from surgery/radiotherapy. Resistance to ADT was defined as the time from ADT initiation to two consecutive rises of PSA greater than the PSA nadir or progression of bone lesions [20,21].
The time intervals between visits to the clinic were those routinely in use and determined by international, namely European, guidelines [20,22]. Information was collected through chart review.

2.2. Genotyping

A venous blood sample (6 ml) was obtained by forearm venipuncture and the white cell fraction used to extract DNA (QIAamp DNA Blood Mini Kit; Qiagen). Blood samples for genetic analysis were collected independent of treatment initiation. The HIF1A +1772 C>T (rs11549465) genetic polymorphism was genotyped by Real-Time PCR using a pre-designed validated Taqman assay (Applied Biosystems). Procedures implemented for quality control included double sampling in about 5% of samples and the use of negative controls in every run.

2.3. Statistical analysis

The Kolmogorov–Smirnov test was used to assess departure from normality of continuous variables, while medians and interquartile ranges were used as descriptive statistics. The Mean differences between groups for data not normally distributed was compared by Mann–Whitney or Kruskal–Wallis tests. The departure from Hardy-Weinberg equilibrium for HIF1A +1772 C>T polymorphism in the non-prostate cancer group was tested by Pearson’s chi-square.

Unconditional logistic regression was used to estimate age-adjusted odds ratios (aORs) and 95% confidence intervals (95%CIs) for the associations between the polymorphism and development of prostate cancer based on additive, recessive and dominant genetic models (additive, CC versus Ct versus tt, and based on the minor allele: dominant, CC versus Ct + tt; recessive, CC + Ct versus tt). We examined the association of HIF1A +1772 C>T genetic polymorphism with overall prostate cancer and restricted to high-grade prostate cancer (combined Gleason score ≥7) in comparison with controls non-cancers.

Serum PSA at diagnosis was stratified according to a 20 ng/ml cutoff, the combined Gleason score was stratified into two groups (<7 versus ≥7), whereas clinical stage was further stratified as localised (T1–T2) or advanced (defined as a tumour invading and extending beyond the prostate capsule and/or extending into adjacent tissue, involving regional lymph nodes and/or distant metastatic sites). The time-to-resistance to ADT was calculated as the interval (in months) since the beginning of ADT until the date of resistance to ADT or last visit.

Empirical analyses were conducted to determine covariates for multivariate models. For time-to-event analyses, age-adjusted Cox regression models were used to assess risk of ADT resistance, whereas age-adjusted logistic regression models were used to evaluate the risk for metastasis. Then, multivariate analysis included relevant clinical variables from empirical evaluation and genetic models. A multivariate Cox proportional hazards model was derived to identify the independent predictive risks for biochemical progression under hormonal castration, while a multivariate logistic regression model was performed to evaluate clinical and genetic predictive factors for prostate cancer metastasis. Statistical analyses were done using STATA version 10.0 (StataCorp, College Station, Texas).

3. Results

One-thousand four hundred ninety individuals were included in this study, 736 cancer-free controls and 754 with a positive biopsy for prostate cancer (median age, 66.8 and 68.0 years old, respectively, \( p = 0.001 \)). Biopsy findings in the control cancer-free group revealed normal histology (10.9%), benign prostatic hyperplasia (33.4%), chronic prostatitis (55.2%) and atrophy (0.5%). As expected, PCa patients presented significantly higher serum PSA levels at diagnosis (\( p < 0.0001 \)).

HIF1A +1772 (rs11549465) genotype distribution by group and risk analysis is shown in Table 1. Both additive and dominant genetic models were not associated with prostate cancer risk or high grade disease. The distribution of HIF1A +1772 C>T genotypes among the non-cancer control subjects were in agreement with Wardy–Weinberg equilibrium (\( p = 0.988 \)). Furthermore, we found that this SNP was not associated to earlier onset of disease, using Kaplan–Meier plots and functions (data not shown).

In the group of prostate cancer patients, analyses of the association between HIF1A +1772 genetic variants and patient’s clinicopathological characteristics showed over-representation of T-allele in the group of patients not treated with definitive therapy (\( p = 0.05 \)) and who developed metastasis at any time during the course of malignant disease (Table 2).

From the group of 754 patients with prostate cancer, 429 were eligible for androgen deprivation therapy, either due to advanced disease at diagnosis or due to disease progression. The clinicopathological characteristics of this nested group are shown in Table 3. From the group of patients on ADT, 194 (45.2%) developed resistance to hormonal therapy. The median (95%CI) follow-up time was 91.8 (79.8–103.7) months.

Univariate age-adjusted empirical time-to-ADT resistance analysis on clinical covariates showed that Gleason grade ≥7 (HR, 2.8; 95%CI, 2.0–4.1), advanced clinical stage (HR, 3.7; 95%CI, 2.5–5.3), definitive treatment (HR, 0.6; 95%CI, 0.4–0.8), PSA ≥ 20 ng/ml (HR, 1.9; 95%CI, 1.5–2.6) and presence of metastasis at ADT initiation (HR, 2.9; 95%CI, 2.1–3.9) were all
Hypoxia is a frequent event during prostate cancer progression, while the hypoxia-responsive gene \textit{HIF1A} codes for a key transcription factor that has been proposed as a modulator of PCa initiation and progression [23–25]. We analysed a functional SNP (+1772 C>T) in the \textit{HIF1A} gene in prostate cancer patients and controls and found lack of association, although a relatively large population with approximately 1500 men was analysed. Concordantly, two large case-control studies from the United States of America and China also observed no risk for having PCa in carriers of this polymorphism [19,26], even though opposite results have also been reported [16,27]. The C-by-T substitution in the +1772 locus at the oxygen-dependent domain of the \textit{HIF1A} gene results in a proline-to-serine substitution and was shown to stabilise \textit{HIF1A} and enhance its activity as a transcription factor in both normoxia and hypoxia [12,28]. In agreement, albeit we hypothesised those carriers of T allele were more susceptible to have cancer, our data, together with other, suggest no influence in earlier stages of prostate cancer development. As PCa natural history usually reveals slow growing indolent tumours, the initial steps of carcinogenesis are not likely to be relevant sources of hypoxia, thereby inducing the

activation of other than the HIF1a pathway. Actually, a previous report found that HIF1A +1772 C>T genotypes were not correlated with HIF1a and VEGF expression in localised prostatic tumours [16]. However, HIF1a overexpression has been reported in cancer precursor lesions, high grade prostate intraepithelial neoplasia, and early stage PCa, compared with normal prostate epithelium [24].

Previous studies have shown overexpression of HIF1a in many tumours with advanced grade, implying HIF1a as an independent prognostic factor in cancer [15]. In addition, increasing evidence suggests that genetic markers may be independent predictors of outcome in PCa with various SNPs predicting decreased progression-free and overall survival [3–6]. Data presented here show that the homozygous T genotype T allele of HIF1A +1772 C>T is associated with increased relapsing after ADT, whereas the T allele is prone to higher risk for having distant metastasis, still after adjustment for empirical covariates (adjusted by Gleason grade, clinical stage and PSA ≥ 20 ng/ml for the risk of metastasis; and by Gleason grade, clinical stage, PSA ≥ 20 ng/ml, definitive therapy and existence of metastases at the time of hormonal castration initiation for the risk of disease recurrence after ADT). While the recessive model (TT versus CT/CC) was significantly associated with resistance to ADT, the dominant (TT/CT versus CC) and additive models were significant for metastasis development under ADT. A recently published meta-analysis suggests that both the T allele and TT genotype were significantly associated with increased cancer risk [17]. Experimental data also support a functional role for the C-by-T substitution at the allele and homozygous genotype level [12,28,29]. We found that additivity was better fitted for metastasis but not to ADT resistance, even though the low number of patients carrying the TT genotype in metastasis analyses yielded a very wide CI, hence deserving careful interpretation.

Our findings in a large cohort of patients that received ADT, support a role for HIF1a in the pathophysiology of castration resistance and the HIF1A +1772 C>T polymorphism as a potential pharmacogenomic predictor of the response to ADT. Concordantly, a recent study demonstrated that HIF1a expression contributed both to metastasis and chemo-resistance of castration resistant prostate cancer [30]. A study comparing HIF1A +1772 C>T genotypes between castration-resistant PCa and non-cancer men showed that the T-allele was overrepresented in the cancer group, although it was not associated with survival [18]. Noteworthy, this report presents data from 196 castration-resistant

patients using univariate analysis. Another study observed a somatic rare mutation at the same locus in 1/15 androgen-independent prostate tumours, whereas functional studies demonstrated in androgen-independent prostate cancer cells that the T-allele is associated with increased transcriptional activity and protein expression [28]. Therefore, we hypothesise that carrying the T-allele, which stabilises HIF1a protein and upregulates the HIF1A1 gene expression, may offer a selective advantage to androgen-independent tumour cells through the upregulation of several genes involved in metastasis, angiogenesis, epithelial-to-mesenchymal transition or in other cancer-associated mechanisms [10,23,31–33]. The SNP in HIF1A at locus +1772 represents a germline variant, suggesting a cumulative impact of higher HIF1a expression since birth. However, we hypothesise that HIF1A+1772 functional SNP repercussion when combined with hypoxic environmental events or with other genetic risk factors is triggered to higher extent in response to hypoxia-inductive treatments such as ADT. When confirmed in larger and independent samples, additional therapeutic schemes (such as CYP17A1 inhibitors or chemotherapy) could be offered to carriers of the poor responder TT genotype as alternative to ADT. These patients could also be enrolled in clinical trials with drugs that target HIF1a function (e.g. tasquinimod and other agents that target HIF1a or its downstream products) [34–37].

Present findings should be further extended and replicated by future studies focusing on genetic polymorphisms as predictors of treatment response to allow tailored therapy in PCa patients. Using this focused candidate gene approach to evaluate the HIF1A +1772 C>T SNP gives us an incomplete analysis of hypoxia mechanism. Other hypoxia-related SNPs were not included in this study. However, our study has several strengths such as the selection of the candidate gene based on biological evidence of functional importance; statistical analyses accounted for relevant clinical and pathological factors. In this study all men (including the controls) were screened for prostate cancer based on both PSA level and digital rectal exam during the recruitment period and diagnosis was determined by standard biopsy or surgical sample, thus making outcome misclassification unlikely.

Our findings suggest that the HIF1A +1772 C>T might be a useful marker of aggressive PCa, particularly a predictor of the response to ADT, thus a plausible candidate to include in a panel of risk prediction SNPs in combination with clinical and pathologic features.
