Introduction

Anorectal complications in patients with haematological malignancies have long been known [1]. Palma [1] showed a relationship between haematological diseases and an increase in anorectal complications, with anorectal manifestations possibly being the first manifestations of haematological diseases.

Later, Schimpff et al. [2] studied a population of 581 patients and concluded that there is an increase in perianal/perirectal infections in patients with haematological cancers compared with patients with nonhaematological cancers (6.5 vs. 0.5%).

Moreover, the development of anorectal complications has been associated with worse prognosis, with a mortality rate of up to 50% [2–4].

Patients with haematological malignant diseases are immunocompromised and therefore particularly prone to anorectal complications. Multiple etiopathogenic factors have been identified: alterations in mucocutaneous barriers owing to haematological diseases or previous anorectal diseases, predisposition for bacterial invasion, some types of intestinal dysfunction such as diarrhoea or constipation (which can be related or unrelated to therapy), immunosuppression owing to loss of normal leucocyte function or chemotherapy, granulocytopenia with granulocyte counts lower than 500 cells/mm³, thrombocytopenia that leads to delayed healing and opportunistic infections owing to immunosuppression [2,3,5–8].

The diagnosis of an anorectal complication in such patients may be challenging, especially when differentiating between septic or nonseptic complications. A careful proctologic examination should always be performed and should be complemented with radiological imaging (ultrasound or MRI) [8–10].

In the past, incision and drainage in such patients was controversial, owing to the fear of impaired healing in...
immunosuppressed patients, possibly aggravating the local disease progress. Supportive measures such as stool softeners, antidiarrhoeal agents, sitz baths, warm compresses, and antibiotics were the recommended treatments [2,3]. Several studies established the benefits of incision and surgical debridement as the preferable treatments in septic complications, in conjunction with supportive measures, and this is currently the recommended therapy [5,8,10–12].

The evolution of local treatments associated with improvements in the supportive care of patients with neutropenic cancer resulted in a decrease in infection-related morbidity and mortality [5,7,11,13].

The objectives of this study are to examine the treatment of a contemporary series of patients with malignant haematological diseases and anorectal complications, to identify the risk factors for anorectal complications in a contemporary series of these patients, to shed light on the results of treatment and to shed light on the actual mortality rate.

Patients and methods

Patients

We retrospectively reviewed the medical records of all patients admitted to the Haematology Department of Central Lisbon Hospital Center from January 2010 to September 2015 who had at least one proctological evaluation during the admission episode. This included only adult patients who were 18 years old or older.

All patients who were younger than 18 years or older than 80 years, had HIV 1 and 2 infections, had inflammatory bowel disease, were pregnant, did not have haematological malignancies, had other oncological diseases or showed incomplete data were excluded. Patients with proctological diseases diagnosed in the year before the admission were also excluded.

The study was approved by the ethics committee.

Variables

A detailed review of medical records was performed to retrieve demographic data and disease-related and treatment-related details regarding both haematological and proctological disorders.

Only blood cultures performed in the 3 days before and 3 days after proctological evaluations were considered. Blood cultures were performed for all patients with fevers or when their haematologist considered them necessary. The absolute neutrophil counts at the time of the development of the anorectal complications were recorded. A gastroenterologist expert in proctology performed the diagnoses of the anorectal complications based on clinical symptoms and physical examination. When necessary, the diagnosis was complemented by MRI, endoanal ultrasonography and/or examination under anaesthesia.

Anorectal complications were classified into two groups: nonseptic complications and septic complications. Nonseptic complications included anal fissures, haemorrhoidal diseases (including haemorrhoidal disease grades II, III and IV and haemorrhoidal thrombosis) and anorectal ulcers. Septic complications included anorectal abscesses, perianal fistulas [including types 1 (intersphincteric fistula), 2 (trans-sphincteric fistula) and 3 (suprasphincteric fistula) of Park’s classification] [14] and perianal cellulitis.

Inpatient and outpatient records were evaluated during a follow-up period of 30 days to assess the course and the resolution of anorectal complications.

Statistical analysis

Continuous variables were presented as medians and ranges. Categorical variables were presented as proportions.

Comparisons between nonseptic and septic complications according to age, sex, absolute neutrophil counts or positive blood cultures were performed using Fisher’s exact test or \( \chi^2 \)-test as deemed appropriate. A multivariate logistic regression analysis was performed and a significance criterion of \( P < 0.05 \) was defined for analysis.

All statistical analyses were performed using Microsoft Office Excel 2013 (Microsoft Corporation, Redmond, Washington, USA) and STATA 12.1 (StataCorp LP, College Station, Texas, USA).

Results

A total of 100 patients were observed at the proctology department during the allotted time period. Seventeen patients were excluded: one without a haematological malignancy, one over the age of 80 years, one with a HIV 1 infection, two with other concomitant oncological diseases, two with proctological diseases diagnosed in the year before the admission and 10 owing to incomplete data. None of the patients had inflammatory bowel disease or were pregnant. Thus, 83 inpatients with haematological malignant diseases and anorectal complications were included in the present analysis. Table 1 shows the patient baseline characteristics and haematological diseases.

Sixty-eight (81.9%) patients had active haematological diseases, and the rest were in haematological remission and were admitted due to complications related to treatment. Eighty (96.4%) patients underwent chemotherapy within the previous 15 days.

Twenty (24.1%) patients had no neutropenia (absolute neutrophil count \( \geq \) 1500 cells), one (1.2%) patient had mild neutropenia (absolute neutrophil count 1000–1500 cells), five (6.0%) patients had moderate neutropenia (absolute neutrophil count 400–600 cells), one (1.2%) patient had severe neutropenia (absolute neutrophil count \( < \) 400 cells)

(absolute neutrophil count 500–1000 cells) and most patients [57 (68.7%)] had severe neutropenia (absolute neutrophil count <500 cells). Of the patients with severe neutropenia, 54 had fever (T ≥ 38.0°C).

Blood cultures were not considered for 14 of the patients because they were not performed in the 3 days before and 3 days after the proctological evaluation. Of the 70 patients for whom blood cultures were obtained at the time of anorectal symptoms, cultures were negative in 47 (67.1%) patients and positive in 23 (32.9%) patients. Positive blood culture organisms included: Enterococcus faecium in six (26.1%) patients, Klebsiella pneumoniae in six (26.1%) patients, Escherichia coli in five (21.7%) patients, Enterobacter cloacae in two (8.7%) patients and Acinetobacter baumannii, Pseudomonas aeruginosa, Stenotrophomonas maltophilia and methicillin-resistant Staphylococcus epidermidis in one (4.3%) patient each.

The main proctological complaints in patients with non-septic anorectal complications were proctalgia [43 (76.8%)], rectal bleeding [32 (57.1%)] and prolapse [18 (32.1%)]; in the patients with septic anorectal complications, the main proctological complaints were proctalgia [26 (96.3%)], perianal tumefaction 17 (63.0%) and discharge [12 (44.4%)]. Diarrhoea was more common in patients with septic anorectal complications [seven (25.9%) vs. 12 (21.4%)] and constipation was more common in patients with nonseptic anorectal complications [12 (21.4%) vs. one (3.7%)].

Most patients [56 (67.5%)] had nonseptic anorectal complications; anal fissures in 30 (36.1%) patients; haemorrhoidal disease grades II, III or IV [including haemorrhoidal thrombosis, six (7.2%)] in 22 (26.5%) patients; and anorectal ulcers in four (4.8%) patients. In this group, conservative treatments (stool softeners, antidepressive agents, sitz baths, warm compresses, oral or topical analgesics, venotropics or antibiotics) or minor proctological procedures (thrombectomy or polidocanol sclerotherapy) were adopted, with an improvement of symptoms or a complete resolution in most patients [48 (85.7%)]. At a 30-day follow-up, seven (12.5%) patients remained symptomatic and one (1.8%) patient died of another cause (pneumonia).

Twenty-seven (32.5%) patients had septic anorectal complications: perianal fistulas in 13 (15.7%) patients (two suprasphincteric fistulas, five trans-sphincteric fistulas and six intersphincteric fistulas), anorectal abscesses in nine (10.8%) patients and perianal cellulitis in five (6.0%) patients. In this group, 12 (44.4%) patients were treated with antibiotics and the remaining 15 (55.6%) patients underwent fistula cannulation procedures and seton placements (and when indicated, fistulotomies) or surgical drainage/debridement in conjunction with antibiotic therapy. At a 30-day follow-up, there was an improvement of symptoms or a complete resolution in 23 (85.2%) patients. Three (11.1%) patients remained symptomatic and one (3.7%) died owing to perianal sepsis. The patient who died was a 41-year-old female with P. aeruginosa bacteremia, a very low neutrophil count (20 cells) and perianal cellulitis. Figure 1 shows the outline of therapeutic management and results.

The overall mortality rate was 2.4% (two deaths), with only one death (1.2%) related to perianal sepsis.

Patients who had septic anorectal complications were more commonly male, were older and had lower absolute neutrophil counts, but no differences were statistically significant in the multivariate logistic regression: male sex (odds ratio (OR) = 1.132, 95% confidence interval (95% CI) = 0.414–3.208, P = 0.786), younger age (OR = 1.266, 95% CI = 0.425–3.769, P = 0.672), low absolute neutrophil count (OR = 1.082, 95% CI = 0.360–3.250, P = 0.889) and positive blood culture (OR = 0.660, 95% CI = 0.227–1.919, P = 0.446) (Table 2).

**Discussion**

Anorectal complications are more frequent in patients with haematological malignant diseases compared with patients with other cancers [1,2]. Early identification of predisposing factors, early diagnosis and prompt treatment are mandatory for reducing morbidity and mortality.

In our study, the major proctological complaints were very similar in patients with nonseptic and septic anorectal complications, with proctalgia being the most common complaint in both groups (83.1%). The differential diagnosis based on patients’ histories can be challenging and should be complemented with careful proctological examinations and radiological imaging [8–10].

All patients were examined by a gastroenterologist expert in proctology under mild sedation or, if necessary, under anaesthesia, and examinations were complemented with MRI or endoanal ultrasonography when necessary. None of the patients with nonseptic complications developed a septic complication during the follow-up period.

Most patients with anorectal complications had active haematological diseases or underwent chemotherapy within the previous 15 days, which seem to be risk factors for anorectal complications; however, these were not statistically analysed owing to a reduced number of patients in the ‘haematologic disease in remission’ and ‘no chemotherapy’ arms.

Previous reports suggest chemotherapy as a risk factor for anorectal complications [2,7].

E. faecium, K. pneumoniae and E. coli were the most common bacteria isolated from blood cultures (73.9%), which was expectable owing to a combination of immunosuppression, colonisation of perianal skin by enteric flora and breaks in anorectal mucosal integrity [6,8]. The positivity for E. coli is similar to previous reports [2,3,5,8,12,15]; however, positive blood cultures for P. aeruginosa were more frequent in other previous studies [2,5,8]. This could be explained because most patients underwent antibiotherapy with a spectrum covering P. aeruginosa. In our series, Enterococcus spp. were more commonly identified than in previous reports [2,3,5,8,12,15].

Others studies should be done to evaluate if Enterococcus spp. infections are increasing in this specific patient population.

Similar to other studies, most patients with haematological diseases and proctological complaints were diagnosed with nonseptic anorectal complications (67.5 vs. 32.5%) such as anal fissures, haemorrhoidal diseases (including haemorrhoidal thrombosis) and anorectal ulcers [3,4,10,15].

In the general population, haemorrhoidal diseases are more common than anal fissures [16,17]; however, in this series of patients with haematological malignancies, anal fissures were more frequent than haemorrhoidal diseases.
(including haemorrhoidal thrombosis), 30 (36.1%) vs. 22 (26.5%), which is presumably owing to their haematological conditions and immunocompromised statuses.

In this group, conservative treatments or minor proctologic procedures were adopted, with either an improvement of symptoms or a complete resolution in most patients (85.7%). Twenty-seven (32.5%) patients had septic anorectal complications such as perianal fistulas, anorectal abscesses and perianal cellulitis, and they were managed with antibiotherapy alone or antibiotherapy in conjunction with fistula cannulation procedures and seton placements (and when indicated, fistulotomies) or surgical drainage/debridement. Most patients (85.2%) achieved either an improvement or a complete resolution of symptoms.

The only death associated with perianal sepsis occurred in a patient with perianal cellulitis in whom a surgical drainage/debridement could not be performed because of the severe neutropenia.

In our study, and similar to previous reports, early incision and surgical debridement in cases of patients with septic complications showed clear benefits and therefore should always be applied when appropriate [5,8,10–12].

The overall mortality rate was 2.4%, with only one (1.2%) death related to perianal sepsis, which was very similar to recent studies and much lower than it was in the past. The improvement in outcomes in recent studies might be attributed not only to adequate management of anorectal complications but also to an improvement in the supportive care of patients with neutropenic cancer [5,7,11,13]. In contrast to other studies, we did not identify an association between septic anorectal complications and possible independent risk factors such as male sex, a younger age, a low absolute neutrophil count or a positive blood culture. A relationship between septic anorectal complications and a younger age was only established in one study [10], but other studies showed a consistent association between a lower absolute neutrophil count and male sex and an increased incidence of septic anorectal complications in patients with haematological diseases [2,4,8–10]. The inability to demonstrate such associations may be owing to the small patient population.

All patients were examined in a single proctology department where the practices between different expert proctologists are very similar, which is a strong point of the study. However, this study has some potential limitations, as it is a single-centre study, has a retrospective study design and has a small study population.

As explained above, future studies aiming to identify the microorganisms implied in these conditions and other possible risk factors may have a significant effect in the identification of at-risk patients, thus improving management of these patients and preventing this condition.

This study demonstrates that nonseptic anorectal complications can be managed with conservative treatment; however, surgical debridement or proctologic procedures should often be applied in cases of septic complications, which have better prognoses now than in the past.
